THE AGE-METALLICITY RELATION OF THE UNIVERSE IN NEUTRAL GAS: THE FIRST 100 DAMPED Lyα SYSTEMS

JASON X. PROCHASKA[1,2], ERIC GAWISER[1,3,4,5], ARTHUR M. WOLFE[1,3], SANDRA CASTRO[1,6,7], S. G. DJORGOVSKI[1,6]

Submitted to Astrophysical Journal Letters: May 8, 2003

ABSTRACT

We present accurate metallicity measurements for 121 damped Lyα systems at $0.5 < z < 5$ including ≈ 50 new measurements from our recently published Echellette Spectrograph and Imager surveys. This dataset is analysed to determine the age-metallicity relation of neutral gas in the universe. Contrary to previous datasets this sample shows statistically significant evolution in the mean metallicity. The best linear fit rate to metallicity vs. redshift is -0.26 ± 0.06 dex corresponding to approximately a factor of 2 every Gyr at $z = 3$. The DLA continue to maintain a floor in metallicity of $\approx 1/700$ solar independent of observational effects. This metallicity threshold limits the prevalence of primordial gas in high redshift galaxies and stresses the correspondence between damped systems and star formation (i.e. galaxy formation). This floor is significantly offset from the metallicity of the Lyα forest and therefore we consider it to be more related to active star formation within these galaxies than scenarios of enrichment in the very early universe. Finally, we comment on an apparent 'missing metals problem': the mean metallicity of the damped systems is $\approx 10\times$ lower than the value expected from their observed star formation history. This problem is evident in current theoretical treatments of chemical evolution and galaxy formation; it may indicate a serious flaw in our understanding of the interplay between star formation and metal production.

Subject headings: galaxies: abundances — galaxies: chemical evolution — quasars : absorption lines

1. INTRODUCTION

For the past decade researchers have observed the damped Lyα systems (DLA) – quasar absorption line systems with H I column density $N(\mathrm{HI}) > 2 \times 10^{20}\,\mathrm{cm}^{-2}$ – to trace cosmological properties of neutral gas in the early universe. With moderate resolution spectroscopy, for example, observers have taken a census of the H I mass density Ω_{gas} from $z = 0$ to 5 and found damped Lyα systems to comprise most of the neutral gas out to at least $z = 4$ (Wolfe et al. 1986; Lanzetta et al. 1995; Wolfe et al. 1995; Storrie-Lombardi and Wolfe 2000; Rao & Turnshek 2000; Péroux et al. 2001; Djorgovski et al. 2003). By combining these observations with higher resolution spectroscopy of metal-line transitions, one tracks the metal enrichment of the universe in neutral gas (Pettini et al. 1994, 1999; Prochaska & Wolfe 2000). If the individual DLA metallicity measurements are weighted by their corresponding H I column densities, the resulting mean represents a cosmological quantity: $\Omega_{metals}/\Omega_{gas}$, which equals the mass-weighted metallicity $< Z >$ of neutral gas in the universe (Lanzetta et al. 1995). Aside from selection biases, this statistic is independent of any physical property (e.g. mass, morphology) of the damped systems surveyed and, therefore, it presents a fundamental test for theories of chemical evolution (e.g. Pei & Fall 1995; Somerville, Primack, & Faber 2001). In turn, these observations constrain the star formation history of the universe and help describe the interplay between nucleosynthesis and gas enrichment in high redshift galaxies.

Because $< Z >$ is a $N(\mathrm{HI})$-weighted measure, the uncertainty in this statistic is dominated by the damped systems with the highest product of metallicity and H I column density. This is analogous to measurements of Ω_{gas} where damped systems with the largest $N(\mathrm{HI})$ dominate the uncertainty[8]. For this reason, previous metallicity samples were susceptible to severe sample variance, systematic error, and potential outliers. With the goal of reducing the effect of small number statistics, we initiated a program (Prochaska, Gawiser, & Wolfe 2001) with the Echellette Spectrograph and Imager (ESI; Sheinis et al. 2002) to rapidly increase the sample of high z damped systems with accurate metallicity measurements. In comparison with previous echelle observations, this instrument and observing strategy have led to a nearly 10x increase in efficiency. In roughly 5 nights observing time, we have doubled the number of $z > 1.5$ damped systems and nearly quadrupled the systems at $z > 3$ (Prochaska et al. 2003a,b). In this Letter, we report the principal results on chemical evolution from our ESI surveys of the damped Lyα systems. Combining these new measurements with ≈ 50 damped systems drawn from the literature, our analysis includes a sample of over 100 damped Lyα systems from $z = 0.5$ to 5.

[8] This effect is less severe at $z > 4$ where there are fewer DLA with $N(\mathrm{HI}) > 10^{21}\,\mathrm{cm}^{-2}$ (see Péroux et al. 2001)

2. THE SAMPLE

At present over 300 damped Lyα systems have been identified in the literature (Curran et al. 2002). Of these, approximately half provide a metallicity estimate. Unfortunately, these metallicity measurements are derived from a variety of telescopes with a range of instrumentation and therefore form a heterogeneous sample of data (e.g. varying resolution, wavelength coverage, and S/N). In this Letter, we primarily restrict[9] our analysis to damped Lyα systems observed on the current generation of large telescopes (e.g. Keck and the VLT) with high-resolution ($R > 5000$), high S/N (> 15 per pixel) spectra. Although this is a subjective observational criterion, there are many cases of understated statistical error and under-appreciated systematic error in the literature for data of poorer quality. We also limit the analysis to systems satisfying the strict $N(\mathrm{HI}) \geq 2 \times 10^{20}\,\mathrm{cm}^{-2}$ criterion. This practice facilitates comparisons with statistical surveys of the damped systems and simplifies comparisons with theoretical models.

Table 1 lists the name, z_{abs}, N(HI), metallicity [M/H], Fe abundance [Fe/H], and reference for the 121 DLA comprising the complete sample. In columns 4 and 6 we list two 'flags' which describe the derivation of the [M/H] and [Fe/H] values. The latter are determined primarily from Fe II transitions or when necessary Cr II, Ni II, or Al II transitions offset by their typical [X/Fe] value (e.g. Prochaska & Wolfe; hereafter, PW02). When possible, we adopt an [M/H] value based on an observed α-element (e.g. Si, S) or Zn. These elements are mildly or non-refractory and should exhibit minimal depletion in the damped Lyα systems. Furthermore, these elements exhibit solar relative abundances with few exceptions (PW02). In cases where there are only limits reported to these abundances and the limits span an interval less than 0.4 dex (e.g. ±0.2 dex), we adopt the central value and an error encompassing the two limits. As a last resort (8 cases), we adopt an [M/H] value calculated from [Fe/H] assuming an offset of 0.4 dex. We consider this robust because the median and mean [α/Fe] and [Zn/Fe] values for DLA at $z > 2$ are all close to 0.4 dex (PW02).

We present the full set of [M/H] values as a function of z_{abs} in Figure 1. The dark, unbinned points identify the data drawn from our recent ESI surveys while the light unbinned points are drawn from our echelle measurements and those of others reported in the literature. The error bars represent the statistical uncertainty in these measurements. For the majority of these observations, this error is dominated by the uncertainty in N(HI) measurements, an uncertainty that is typically not rigorously derived. The quoted values tend to overestimate the statistical error and underestimate the systematic error from line-blending and continuum placement. In the following analysis, we adopt a minimum error of 0.1 dex for all metallicity measurements. It is important to emphasize, however, that none of the analysis in this Letter is sensitive to statistical error related to individual measurements.

3. ANALYSIS

In Figure 1 we overplot the unweighted, logarithmic mean metallicity (i.e. the mean of [M/H] values) in 5 redshift bins at $z > 1.5$ defined to have equal numbers of DLA and one redshift bin with $z = [0.5, 1.5]$ covering the damped systems with Lyα profiles at $\lambda_{obs} < 3100$Å. This statistic was chosen to best represent the evolution in the metallicity of a 'typical' damped system as seen by eye in the log-linear plot in Figure 1. The vertical error bars report *95% c.l. uncertainty* in this mean value as determined from a bootstrap error analysis. Meanwhile, the redshift marked for each bin refers to the median z_{abs} value. Even an eyeball analysis of the figure reveals a statistically significant evolution in the unweighted mean metallicity. Performing a least-squares linear fit to the binned data (which best accounts for the scatter in the measurements), we calculate a slope $m = -0.26 \pm 0.06$ dex/Δz and zero-point $[\mathrm{M/H}]_0 = -0.67 \pm 0.17$ dex. The results indicate that the metallicity of the 'average' galaxy is increasing with decreasing redshift with an e-folding time of approximately 1 unit redshift, i.e., a 2× decrease per Gyr at $z \sim 3$. This statistically significant evolution in the unweighted mean contrasts with our previous samples, although Vladilo et al. (2000) suggested such a trend at $z < 3$ in a much smaller sample. We note that the y-intercept of the best-fit line is nearly 4σ below solar metallicity. This may be an indication of small sampling at low z or our assumption that the logarithmic mean metallicity evolves linearly with redshift. On the other hand, it is possible that a cross-section selected sample of H I gas at $z = 0$ (e.g. Rosenberg & Schneider 2003) would show a sub-solar metallicity due to the contributions from dwarf and low surface-brightness galaxies.

The cosmological mean metallicity $< Z >$ was computed using $< Z >= \log[\sum_i 10^{[M/H]_i} N(\mathrm{HI})_i / \sum_i N(\mathrm{HI})_i]$ and is presented in Figure 2 in the same six bins. In the figure, the individual measurements are now represented by squares whose areas scale with the N(HI) values of the DLA. Because the $< Z >$ statistic is dominated by the DLA with the largest N(HI) and [M/H] values, its measurement uncertainty will always be dominated by sample

---

[9] The exceptions are the $z < 1.5$ damped systems which include an estimate from X-Ray observations (Junkkarinen et al. 2003, in preparation).

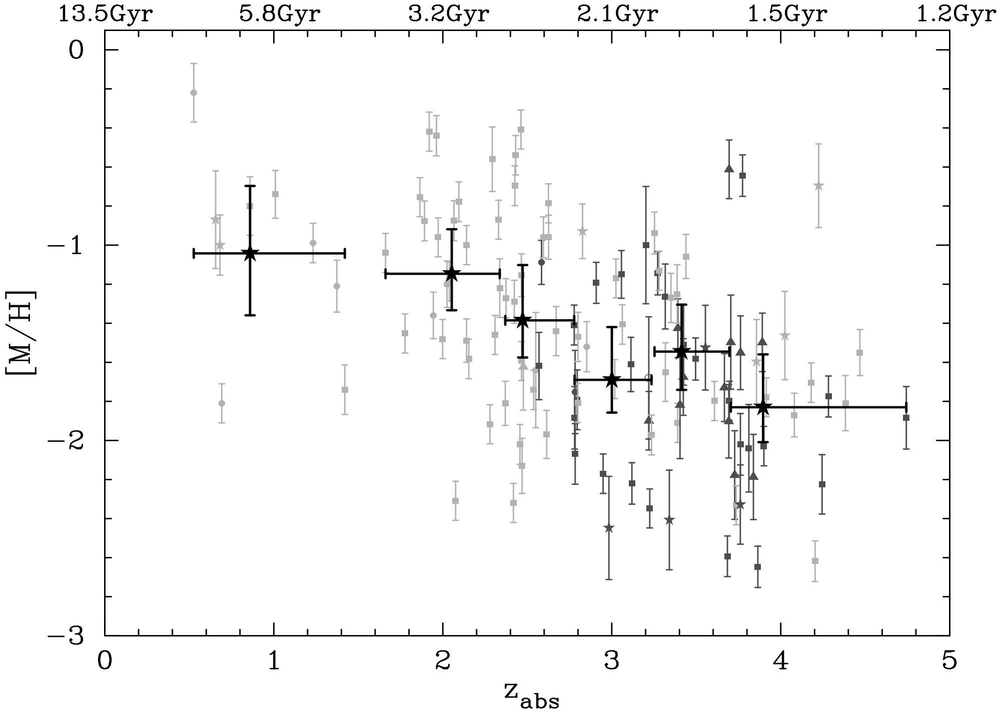

FIG. 1.— The [M/H], z_{abs} values for the 121 damped systems comprising our complete sample. The darker points indicate the new values from our ESI surveys while the lighter data points are all taken from the literature (primarily HIRES and UVES observations). The symbols for the points indicate the origin of the [M/H] values: α-element measurement (filled squares); Zn measurement (filled circle); α+Zn limits (filled triangle); Fe measurement + 0.4 dex (filled star); Fe limits + 0.4 dex (open circle). A trend of lower metallicity at higher redshift is clearly evident in the figure. We evaluate this trend by measuring the unweighted mean metallicity in the 6 bins (solid star points with error bars). A least-squares fit to these data points yields a best fit slope of $m = -0.26 \pm 0.06$ dex. The error bars plotted on the binned data represent 95% c.l. derived from a bootstrap error analysis.

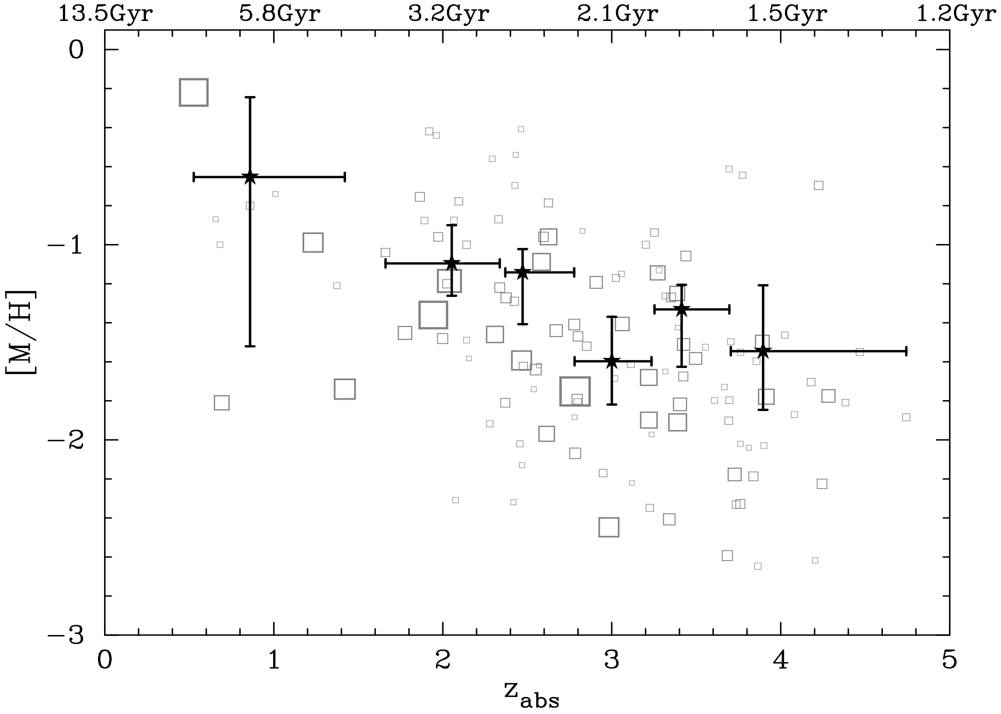

FIG. 2.— The [M/H], z_{abs} pairs are plotted as open squares where the area of each square is scaled to the N(HI) value of the damped system. This aids the eye in determining which sightlines dominate the N(HI)-weighted, cosmic mean metallicity. The cosmic metallicity $< Z >$ is plotted for 6 bins with 95%c.l. uncertainties given by a bootstrap analysis. Similar to the unweighted mean, we find a best fit slope of $m = -0.25 \pm 0.07$ dex assuming a linear solution to the $< Z >$ vs. z_{abs} values.

variance as opposed to statistical error. We estimate this variance through the bootstrap technique and the vertical error bars refer to 95% c.l. on the mean. The bootstrap technique assesses the sample variance under the assumption that the observed distribution is not severely different from the true, underlying distribution. If the data sample is too small, even a single outlier could significantly change the central value of the mean statistic significantly beyond the error implied by a bootstrap analysis. While this issue was a concern in previous analyses, the results at $z \approx 2-4$ are now robust to all but the unlikeliest of outliers. For example, the discovery of a system with $N(\mathrm{HI}) = 10^{22}\,\mathrm{cm}^{-2}$ and 1/3 solar metallicity would only increase $< Z >$ by $\approx +0.2$ dex in the $z \sim 2$ bin or $+0.25$ dex at $z \sim 3.5$ (see also Prochaska 2003b). Such an outlier would lie nearly a factor of 10 off the current $N(\mathrm{HI})$, [M/H] distribution and it would necessitate an entire population of DLA separate from the 100 sightlines presented here. This population could only exist if the current sample is significantly biased by selection effects (e.g. dust obscuration), an assertion unsupported by any recent observational test (e.g. Ellison et al. 2001; PW02).

Performing a least-squares fit to the $< Z >$ values, we find $m = -0.25 \pm 0.07$ and $b = -0.61 \pm 0.21$ dex. Note that the inclusion of the $z < 1.5$ bin has minimal impact on this analysis. Somewhat to our surprise, especially given the impression from a visual inspection of Figures 1 and 2, the best fit slope to the $< Z >$ values is identical within statistical uncertainties to the value derived for the unweighted mean. This marks the first demonstration of evolution in $< Z >$ at greater than 3σ confidence. In this case, our analysis implies that the mean metallicity of the universe in neutral gas is approximately doubling every billion years from $z = 4$ to 2.

4. DISCUSSION

The history of metallicity in the universe provides a potentially powerful constraint on models of galaxy formation, and it is tempting to draw additional conclusions from the distribution of points in the figures. The scatter amongst the points in each bin does not appear to evolve with redshift, implying that at each epoch DLA represent a set of systems at various stages in their formation. The interpretation of this is complicated by the unknown breakdown of the observed scatter into scatter amongst galaxies and scatter within galaxies. Sightlines through the DLA provide pinpricks of transverse diameter $\lesssim 10$ pc through the absorbing system. Although DLA abundances show remarkable uniformity amongst multiple components along these sightlines (Prochaska 2003a), we do not know how well the metallicity of the entire galaxy is sampled by these measurements. These characteristics of an evolving mean with nearly constant scatter would like pose a difficult challenge to scenarios which would describe damped Lyα systems as a transient phase in the formation of galaxies.

Another important characteristic of the observed distribution of [M/H],z pairs is the areas of redshift-metallicity space that remain unoccupied. In particular, note the absence of any DLA at $[\mathrm{M/H}] < -3$ at all redshifts and the lack of DLA at $[\mathrm{M/H}] > 0$ at all redshifts. The eye can identify a gradual increase in the maximum and minimum metallicity with redshift at roughly the same rate of evolution as that of the unweighted logarithmic mean, but it would be dangerous to interpret this since the max and min are sensitive to outliers. Regarding the lower limit to the DLA metallicities, it appears possible that we will never identify a damped Lyα system with $[\mathrm{M/H}] < -3$, a value which significantly exceeds our detection limit. This lower bound has important implications for the presence of primordial gas (zero metallicity) within these galaxies. If primordial gas with significant surface density and cross-section exists in high redshift galaxies, then it is always surrounded by metal-enriched gas yielding a mass-weighted metallicity exceeding 1/1000 solar. Alternatively, primordial gas may not exist in the neutral phase within high z galaxies. It may be possible to distinguish between these scenarios by observing the higher order Lyman lines to pursue metallicity measurements of individual DLA components.

This metallicity floor also limits the contribution to DLA from gas 'clouds' which are unrelated to galaxies (e.g. overdense regions associated with large-scale structures). The metallicity floor requires that this gas was enriched to $[\mathrm{M/H}] > -3$, presumably by a nearby galaxy. To match the observed metallicities would probably require fine-tuning, which argues against the likelihood that DLA are anything but galaxies in the early universe. We also emphasize that the lower bound to the metallicity of the DLA ($[\mathrm{M/H}] \approx -2.6$) is significantly higher than the metallicities typically attributed to the Lyα forest (e.g. Songaila 2001). This suggests that the lower bound to the DLA values may not be simply related to the physical processes which have enriched the Lyα forest (e.g. pollution from Population III stars). We contend that the offset between the DLA metallicities and the Lyα forest indicates the enrichment of DLA gas at all metallicity is dominated by metal production *within* these galaxies. It is possible, however, that Pop III scenarios would predict larger pre-enrichment in regions of higher overdensity, perhaps even to the lower bound observed for the DLA.

A key implication of our results comes to light in their comparison with the recent determination of DLA star formation rates (Wolfe, Prochaska, & Gawiser 2003). Although it is not yet possible to compare the metallicity and integrated star formation rates of individual DLA, it *is* possible to compare the average DLA metallicity at $z = 2.5$ with the integral under the cosmic star formation history at $z > 2.5$ (Wolfe, Gawiser, & Prochaska 2003). The comparison illustrates a "missing metals problem" for the DLA: the integrated SFR's measured for the DLA combined with a standard IMF and yield of heavy elements imply 10× the mass density of metals observed in the damped systems. This conflict suggests scenarios where the metals are ejected from the galaxy via supernovae feedback or where the metals are sequestered within the star formation regions for significant timescales (e.g. within a galactic bulge; Wolfe, Gawiser, & Prochaska 2003). It is also possible that the mean metallicities of the typical DLA systems are not representative of those in the actual star forming regions. Observations of absorption systems associated with GRBs, which probably do probe the star forming regions themselves, suggest higher metallicities which may be more typical of disk stellar populations (see, e.g., Mirabal et al. 2002, Savaglio et al. 2003, or Djorgovski et al. 2003, and references therein). A fundamental uncertainty in comparing the actively star forming regions sampled by GRBs and that of the majority of the neutral gas in the universe sampled by the DLA is our lack of understanding of the mixing efficiency of metal enrichment. More detailed modeling is needed before this issue can be completely resolved.

This problem is evident in recent theoretical models of chemical evolution which consider the mean metallicity of the universe in neutral gas (Pei, Fall, & Hauser 1999; Somerville, Primack, & Faber 2001; Tissera et al. 2001; Mathlin et al. 2001; Cen et al. 2003). These treatments range from analytic chemical evolution scenarios (i.e. independent of galaxy formation models) to full-blown hydrodynamic, numerical simulations. The analyses appear to offer a wide range of theoretical values for the mean metallicity of the universe in neutral gas, yet the majority of variation stems from two key factors: (1) the adopted (or predicted) star formation history; and (2) the treatment of selection biases due to dust obscuration. An appreciation of these two aspects can be obtained by following the analysis of Somerville, Primack, & Faber (2001) who focused on the stellar properties of the Lyman Break Galaxies. In addition to discussing their predictions for the star formation history of the early universe, the authors examined the mean metallicity in cold gas. In all of their scenarios, the values exceeded the damped Lyα observations by at least a factor of 3 at all redshifts $z > 2$. This discrepancy is a restatement of the "missing metals problem" described above. At present, the star formation history implied by various studies of high-z galaxies (including DLA themselves) produce too many metals in comparison with the DLA. This is a universal characteristic of these chemical evolution models, even in those scenarios which underpredict the star formation history at $z > 2$ (e.g. Pei, Fall, & Hauser 1999; Mathlin et al. 2001).

Several of the theoretical treatments, however, report successes in matching previous DLA metallicity samples. In all of these cases, the authors introduced significant selection biases owing to the effects of dust obscuration. Undoubtedly, dust obscuration plays a role in observations of the damped Lyα systems, especially at lower redshift where the gas metallicity and dust content are presumably highest. At $z > 2$, however, current samples of DLA toward radio-selected quasars exhibit no significant difference from optically-selected samples (Ellison et al. 2001b). Furthermore, PW02 found no dependence between the inferred dust opacity of observed DLA sightlines and the quasar magnitude, contrary to expectation in scenarios where dust obscuration is important. The original claims of reddening by Pei, Fall, & Bechtold (1991) have not been confirmed by larger, homogeneous quasar samples, e.g., Outram et al. (2001) found only a 2σ indication of reddening in their $z \lesssim 1$ 2dF quasar sample. At present, we believe there is no compelling evidence for dust obscuration[10] beyond its convenience as a possible solution to the missing metals problem. Regarding this aspect, we emphasize that no group has self-consistently matched the observed star formation history of the early universe with the metallicity measurements observed for the damped systems even when allowing for dust obscuration. Current theories of star formation and metal production in high redshift galaxies are missing a vital aspect of the processes.

Looking toward the future, observations of 300 additional DLA are needed to bring the statistical error at $z = 2$ to 4 down to the level associated with systematic effects such as differential depletion. With the introduction of ESI and similar future instrumentation, we expect this will be accomplished within the next decade. Significant gains, meanwhile, can be made very quickly at $z < 1.5$ and $z > 4$ owing to the small sample size. Unfortunately, measurements at $z < 1.5$ are slowed by the requirement of ultraviolet observations. This is a particularly challenging aspect of damped Lyα research because this redshift range corresponds to over half the age of the current universe. While the COS spectrograph on the Hubble Space Telescope will improve the situation, a comprehensive view of metal enrichment over the past 8 Gyr will require the launch of a 4m-class ultraviolet telescope (Prochaska et al. 2002).

The authors wish to recognize and acknowledge the very significant cultural role and reverence that the summit of Mauna Kea has always had within the indigenous Hawaiian community. We are most fortunate to have the opportunity to conduct observations from this mountain. We acknowledge the Keck support staff for their efforts in performing these observations. We would also like to thank M. Pettini for helpful comments. We also acknowledge our collaborators who have allowed us to present several measurements prior to publication. E.G. is supported by Fundación Andes and by an NSF Astronomy and Astrophysics Postdoctoral Fellowship under award AST-0201667. AMW is partially supported by NSF grants AST 0071257. SGD acknowledges a partial support from the Ajax Foundation.
